21  
22 Alkaline activation of fly ash creates a geopolymeric cement that can replace the ordinary  
23 Portland cement in several applications such as soil improvement, with the advantage of much  
24 lower CO<sub>2</sub> emissions and reusing an industrial by-product otherwise landfilled, thus averting  
25 several environmental problems. In this paper, the behavior of a silty sand improved by the  
26 alkaline activation of fly ash is analyzed from small to large strains by presenting uniaxial and  
27 drained triaxial compression tests' results, as well as seismic wave velocities measured  
28 throughout the curing period. The dynamic, cyclic and static tests show a significant increase  
29 in stiffness with curing time, even beyond the 28 days of curing period. Based on the non-  
30 destructive wave propagation technique, the increase of the shear and compression wave  
31 velocities with time were drawn giving the evolution of the elastic shear modulus as well as the  
32 Poisson ratio values. The dynamic Young modulus was compared to the correspondent secant  
33 Young modulus obtained from the mechanical tests. Additionally, the evolution of the  
34 properties of this stabilized soil with curing time was compared and confronted to that of soil-  
35 cement, based on the elastic stiffness of both materials, showing that the most significant  
36 difference lies on the curing rate.

## 41 **Introduction**

42

43 Soil stabilization with cement and/or lime-based binders has been the subject of many research  
44 programs over the last few decades (e.g., Dupas and Pecker, 1979; Little, 1995; Camusso and  
45 Barla, 2009; Consoli et al., 2011; Rios et al., 2012; Houssain and Yin, 2014; Rahimi et al.,  
46 2016). Recently, other materials have been tested successfully for artificial cementation of  
47 soils, like biopolymers (Chen et al., 2014; Khatami and O’Kelly, 2013), polymer-infused roots  
48 (Sauceda et al., 2014), carbonating reactive magnesia (Yi et al., 2013) or microbial-induced  
49 calcite precipitation (e.g., Cheng et al., 2013). The interest in soil improvement is based on the  
50 environmental, economic, social and technical advantages of improving the geotechnical  
51 properties of the original soil, instead of, for instance, replacing it by a soil with better  
52 mechanical properties. However, environmental issues related to cement production and  
53 durability concerns regarding its application to soil layers constitute a significant motivation  
54 to develop new binders. In particular, the amount of carbon dioxide released to the atmosphere  
55 by the cement industry is estimated to represent 5% to 8% of the global carbon dioxide  
56 emissions (Scrivener and Kirkpatrick, 2008). In that sense, the use of increasing volumes of  
57 waste materials, such as fly ash (Kang et al., 2016) in the construction industry is becoming a  
58 more and more significant contribution for the reduction in cement consumption.

59

60 Several studies have recently been made aiming the characterization of alkali activated fly ash  
61 as a possible substitute for traditional Portland cement from the mechanical and environmental  
62 point of view (e.g., Palomo et al., 1999; Turner and Collins, 2013). However, most of them are  
63 focused on structural applications, as a substitute for concrete (e.g., Bernal et al., 2011). The  
64 few studies for soil improvement applications were only based on a high consumption of  
65 alkaline activator (Cristelo et al., 2011, 2013, Sukmak et al., 2013), and the final product was a  
66 viscous grout, with an almost liquid consistency, very different from that of a typical soil-

67 cement mixture. The mechanical behavior of these mixtures is therefore far from that of a lightly  
68 cemented soil. The high levels of activator have also a significant impact on the cost of the  
69 technique, producing strength levels which can be much higher than needed.

70

71 Therefore, this research project intended to characterize the geotechnical behavior of a well  
72 graded silty-sand resulted from remolded residual soil from granite masses, abundant in Porto  
73 region, stabilized with fly ash (FA) activated with low rates of a sodium-based grout. The low  
74 rates of activator are expected to have three major consequences:

75

- 76 - The generation of lower strength levels than those reported in the scarce available  
77 literature regarding soil stabilization with alkali activated fly ash, but still high enough  
78 for most geotechnical applications.
- 79 - The lower percentages of activator will reduce the total cost of the technique, to a level  
80 for what it becomes competitive with cement from a financial point of view.
- 81 - It will also produce a final mixture with a soil-like structure, which will enable the use of  
82 common geotechnical laboratory tests and procedures, namely in the triaxial apparatus.

83

84 In the present paper, the deformation behavior of this stabilized soil is assessed based on  
85 uniaxial and triaxial tests – using local strain instrumentation; and seismic wave analysis - using  
86 ultrasonic transducers, throughout the loading process, from very small to very large shear  
87 strains. This large range characterization is essential to accurately predict the stress-strain  
88 behavior, enabling the design of geotechnical structures with this material. Considering the  
89 extensive worldwide experience of soil-cement behavior (Rios et al., 2014), a comparison  
90 between both materials is presented.

91

92

93 **Materials and Methods**

94

95 This study presents the characterization of mixtures composed by silty sand (characterized in  
96 Viana da Fonseca et al., 2013), fly ash and an alkaline activator. Low calcium content fly ash  
97 (Class F according to ASTM C618, 2003), produced by a Portuguese coal-fired thermo-electric  
98 power plant, was used. The activator was prepared using a sodium silicate (SS) to sodium  
99 hydroxide (SH) ratio of 1:2. The SS was originally in solution form, with a bulk density of  
100  $1.464 \text{ g/cm}^3$  at  $20^\circ\text{C}$ , a  $\text{SiO}_2/\text{Na}_2\text{O}$  weight ratio of 2.0 (molar oxide ratio of 2.063) and a  $\text{Na}_2\text{O}$   
101 concentration in the solution of 13.0%. The SH was originally supplied in pellets with a specific  
102 gravity of 2.13 at  $20^\circ\text{C}$  (99 wt%), and was dissolved in water to form a 7.5 molal solution.

103

104 Three types of mixtures were studied, with different FA percentages (relatively to the total  
105 solids weight), activator contents (liquid to solids ratio) and dry unit weights. Furthermore,  
106 specimens with the same ash contents and a liquid phase constituted solely by water, that is,  
107 without activator, were molded and tested for comparison purposes. Characterization of all the  
108 fabricated mixtures is shown in Table 1. More details may be found in Rios et al. (2016).

109

110 To fabricate the specimens, the dry soil was first mixed with fly ash until a homogeneous  
111 mixture was obtained. Then, the activator solution (produced 6 h before use to allow  
112 temperature stabilization) was added, followed by further mixing. The resulting paste was  
113 compacted in three layers inside a cylindrical stainless steel mold with 70 mm of diameter and  
114 140 mm height in order to obtain the desired unit weight. After 48 h the specimen was removed  
115 from the mold and wrapped in cling film, to avoid moisture loss, before being stored again in a  
116 controlled temperature room ( $20^\circ\text{C}$ ). Curing periods of 28 and 90 days were considered.

117

118 Uniaxial compression strength (UCS) and drained triaxial compression (CD) tests were  
119 performed according to ASTM 1633 (1996) and ASTM D7181 (2011), respectively, on  
120 specimens cured for 28 (UCS and CD) and 90 days (UCS). A 100-kN automatic hydraulic  
121 testing machine was used for the uniaxial compression strength (UCS) tests, fitted with a 50-  
122 kN capacity and 0.006-kN resolution load cell (Figure 1a). For reproducibility reasons, each  
123 UCS result is the average of three tested specimens. The tests were carried out under monotonic  
124 displacement control, at a rate of 0.1 mm/min. This speed is slower than the value recommended  
125 by ASTM 1633 (1996), so that it could be possible to perform small unload-reload cycles. Local  
126 deformation transducers (LDTs) were used with the UCS tests for increased strain measurement  
127 accuracy (Goto et al., 1991; Hayano et al., 1997) and, consequently, more reliable unload-reload  
128 stiffness moduli (Figure 1b). These small unload-reload cycles were included in some UCS  
129 tests, at 15%, 30% and 60% of the expected uniaxial compression strength. The cycle amplitude  
130 ( $q_{cyc}^{max} - q_{cyc}^{min}$ ) was established at 20% of the maximum deviator stress of each cycle ( $q_{cyc}^{max}$ ).  
131

132 Triaxial tests were performed using Hall-effect Transducers (Clayton et al., 1989) glued directly  
133 onto the specimen membrane (Figure 2). The specimens were saturated applying a back-  
134 pressure of 500 kPa, anisotropically consolidated considering a coefficient of earth pressure at  
135 rest ( $K_0$ ) of 0.5, and sheared under displacement control at a rate of 0.01 mm/min. During the  
136 triaxial tests, unload-reload cycles were performed at 5%, 15%, 30% and 60% of the  
137 corresponding unconfined compressive strength, assuming that this value is a lower bound  
138 estimate of the peak deviator stress. A large amplitude ( $q_{cyc}^{max} - q_{cyc}^{min}$ ) of 90% of the  $q_{cyc}^{max}$  was  
139 used, allowing a clear definition of the cycle.  
140

141 Ultrasonic compression (P) and shear (S) wave velocities were measured by ultrasonic non-  
142 destructive transducers (Figure 3) in all the UCS test specimens, at the curing periods of 3, 7,  
143 14, 21 and 28 days, and at 90 days for the long-term curing specimens. For wave generation

144 and acquisition, commercially available equipment was used (Figure 3a), comprising a pair of  
145 piezoelectric ultrasonic compression transducers, for measuring P-wave velocities, with a  
146 nominal frequency of 82 kHz and 30 mm in diameter; a pair of piezoelectric ultrasonic shear  
147 transducers, for measuring S-wave velocities, with a nominal frequency of 100 kHz and 35 mm  
148 in diameter; and a pulse waveform generator and data acquisition unit, equipped with an  
149 amplifier, directly logged to a PC, using specific software to operate as an oscilloscope.

150

151 The input signal was configured for an excitation voltage of 500 V and a pulse signal frequency  
152 of 82 kHz, both for P and S-wave transducers. The same frequency was used for both  
153 transducers since this is the closest frequency available in the function generator. Calibration  
154 of each pair of transducers was achieved by measuring the wave velocity through a calibration  
155 rod, with known density and wave velocity. The measurements were taken along the  
156 longitudinal axis of the specimens, with the specimen vertically aligned and the transducers  
157 installed on opposite faces. Therefore, the path length corresponded to the height of the  
158 specimens of approximately 140 mm. The exact travel length and the weight of each specimen  
159 were measured before each reading, with a precision of  $\pm 1\%$ . In terms of wave propagation, the  
160 transmitter was located at the bottom of the specimen, while the receiver was at the top end.  
161 The acoustic coupling between the transducers and the specimen during the measurement was  
162 ensured by a layer of ultrasound conductive gel. Furthermore, the transducers were firmly and  
163 uniformly pressed against the top surface of the specimen, by the use of a 1 kg disk (Figure 3b)  
164 assuring a similar pressure on the transducers throughout the entire experimental program. The  
165 readings were taken at generic curing periods of 3, 7, 14, 21, 28 and 90 days. Each presented  
166 result corresponds to the average of at least ten consecutive pulse velocity readings.

167

168

169

## 170 **Results**

171

### 172 *Assessment of stiffness by compression tests*

173

174 The unload-reloading cycles performed on the unconfined compression tests allowed the  
175 evaluation of the unload-reload modulus ( $E_{ur}$ ) at three different strain levels, as expressed in  
176 Figure 4 for mixture M2 after 90 days curing. From the stress-strain curves the secant stiffness  
177 modulus was determined, using the values plotted in Figure 5 against the deviator stress  $q$   
178 normalized by its peak value ( $q_{peak}$ ). The secant moduli are significantly higher in the alkali  
179 activated mixtures than in non-activated soil-ash specimens. A clear difference was also  
180 observed between the two curing times (28 and 90 days) at all stages of these UCS tests,  
181 including at peak (where bonding has been partially destroyed) meaning that a strong type of  
182 bonding is present (Cuccovillo and Coop, 1999). On the other hand, the stiffness degradation  
183 pattern appears to be steeper at 90 days than at 28 days, as typically happens when cementation  
184 increases (Leroueil and Vaughan, 1990, Viana da Fonseca et al., 2011).

185

186 Triaxial test results showed very stiff stress-strain curves, as illustrated in Figure 6. Although  
187 large cycles were performed, resulting in considerable yielding, an attempt was made to recover  
188 the elastic modulus considering the initial part of the unloading branch, as reported in Gomes  
189 Correia et al. (2004). Figure 7 illustrates this analysis for one of the tests, namely the test of M2  
190 specimen at  $\sigma_{v0} = 50$  kPa and  $\sigma_{H0} = 25$  kPa.

191

192 As presented for the UCS, the secant modulus evolution during the triaxial compression tests  
193 was also plotted against  $q/q_{peak}$  (Figure 8). The data is very clear indicating that M1 mixture is  
194 definitely the stiffer, and that the confining stress contributed to an increase in stiffness. This  
195 shows that strong cemented bonds (as it is the case in M1) do not break when the confining  
196 stress is applied. In the other mixtures the results are not so evident and it is possible that a

197 weaker type of cementation is present resulting in some damage of cemented bonds due to  
198 confining stress, especially at M3. However, more results were needed to confirm this.

199

#### 200 *Assessment of stiffness by compression and shear wave measurements*

201

202 Compression and shear wave velocities (P and S waves, respectively) were used to evaluate the  
203 development and evolution of the elastic stiffness of the cemented specimens to be tested in  
204 unconfined compression, throughout curing time. This was possible by the non-destructive  
205 nature of these ultrasonic wave measurements. Figure 9 shows the obtained output signal for P  
206 and S waves, indicating the propagation time registered in each measurement, using a classical  
207 time-domain approach. The determination of P-wave travel time is straightforward,  
208 corresponding to the first break of the received wave signal, as clearly indicated in Figure 9a).  
209 On the other hand, the selection of the shear wave arrival is slightly more complex, due to the  
210 interference of compressional waves and near-field effects in the received signal, as previously  
211 recognized by other authors (Arroyo et al., 2003; Viana da Fonseca et al., 2009). As a result, S-  
212 wave arrival was defined as the first major downward break (the polarity of the signals was  
213 determined during calibration), corresponding to the beginning of a low frequency wave,  
214 typical of shear waves, as evident in Figure 9b).

215

216 From the theory of elasticity, it is well known that compression and shear wave velocities are  
217 related to the confined ( $M_0$ ) and shear ( $G_0$ ) moduli, respectively, according to Equations (1) and  
218 (2).

219

$$M_0 = \rho V_P^2 \quad (1)$$

$$G_0 = \rho V_S^2 \quad (2)$$

220

221 where  $\rho$  is the bulk density of the material. Equation (3) provides the Poisson's ratio value ( $\nu$ ),  
222 from which the dynamic Young's modulus ( $E_0$ ) can be derived, using Equation (4).

223

$$\nu = \frac{\left(\frac{V_P}{V_S}\right)^2 - 2}{2\left(\frac{V_P}{V_S}\right)^2 - 2} \quad (3)$$

$$E_0 = 2G_0(1 + \nu) \quad (4)$$

224

225 Figure 10 and 11 illustrate the evolution of these elastic parameters with curing time for the  
226 three different mixtures up to 90 days. Three specimens were molded for each mixture as  
227 expressed by the symbols and the average line is plotted for a clear comparison. A significant  
228 evolution of these moduli with curing time has been found. M1 and M3 mixtures have a parallel  
229 linear trend, although M1 presents higher stiffness evolution. M2 mixture consistently shows a  
230 different behavior, with a trend close to M1 at earlier curing periods but with lower stiffness  
231 values at 90 days of curing time. This may indicate that M2 mixture tends to cure at a faster  
232 rate, stabilizing at an earlier age than the other two mixtures; however, further investigation is  
233 needed to confirm this statement.

234

235 Poisson's ratio also shows an interesting trend slightly reducing at shorter curing times and then  
236 increasing up to 0.25 for M1 and M2 mixtures and 0.3 for M3. Since this has been consistently  
237 observed in all specimens, the inflexion point may be associated with the onset of the chemical  
238 reactions that create the geopolymeric gel bonding the soil particles. The curing process is  
239 associated to the formation of new bonds between particles, creating new blocks of particles  
240 which become larger with time. The increase of the dynamic Poisson ratio value after 7 days  
241 may be associated to the deformation of those blocks when loaded. In order to understand when  
242 this increase of Poisson ratio value will stop, a M1 specimen was molded specifically for this

243 purpose and left to cure for a year. P and S waves were measured in this specimen at 7, 75, 90,  
244 120, 180, 300 and 365 days. The Poisson ratio curve obtained from those measurements is  
245 plotted in Figure 12 being clear that after 90 days (the higher curing time of the previous figure)  
246 the Poisson ratio tends to decrease and stabilize around 0.22. With the development of the  
247 curing process, the cementation tends to homogenize the structure creating a matrix close to  
248 what is found in concrete, dropping the Poisson's ratio values to around 0.20, close to the value  
249 of integer cemented aggregates.

250

251

## 252 **Discussion**

253

254 This section primarily presents the comparison and correlation between stiffness properties  
255 obtained from dynamic, cyclic and static mechanical tests at different strain levels. Table 2  
256 summarizes the data obtained in those tests for the three mixtures at 28 and 90 days of curing,  
257 that is the dynamic Young's modulus ( $E_0$ ), the unload-reload modulus obtained in the cycles  
258 ( $E_{ur}$ ) and the initial tangent stiffness obtained by the initial linear trend of the stress-strain curve  
259 ( $E_{t0}$ ). From the data at 28 days, it is clear that M1 shows higher stiffness than M2 which is also  
260 stiffer than M3. At 90 days, the seismic wave measurements show higher stiffness in M3 than  
261 in M2.

262

263 Due to the very low strain level involved in seismic wave measurements,  $E_0$  corresponds to the  
264 higher stiffness modulus under purely elastic conditions. However, some unload-reload  
265 modulus, performed during triaxial tests at certain stress state in well controlled conditions,  
266 have reached very high values similar to  $E_0$ . In fact, the triaxial test data has to be analyzed  
267 taking into account the effect of the confinement stress state to compare with both the dynamic  
268 and UCS tests which were performed with no confinement. Instead of normalizing the secant

269 stiffness modulus ( $E_{sec}$ ) by the corresponding effective stress, the  $E_{sec}$  was divided by an elastic  
270 stiffness modulus as suggested by Vardanega and Bolton (2013). Since  $E_0$  is, in average, almost  
271 twice the initial tangent moduli of the UCS test (Table 2), and thus considerably different from  
272 the secant stiffness modulus, the  $E_{t0}$  was selected for the normalization of both UCS and triaxial  
273 test data.

274

275 The secant modulus from triaxial tests was therefore divided by the corresponding  $E_{t0}$  presented  
276 in Table 2 so that the degradation pattern of each triaxial test could be analyzed and compared  
277 with the others (Figure 13). For the low stress level, M1 mixture shows higher normalized  
278 stiffness modulus than the other mixtures. However, that does not happen for the other stress  
279 states. In fact it is interesting to notice that mixtures with lower stiffness modulus (such as M3)  
280 have less steeper degradation curves, meaning that a reduction in stiffness may be associated to  
281 a more ductile behavior conversely to the stiffer and fragile mixtures. This is very important  
282 because in some applications, such as road platforms, it may be better to have ductile behavior  
283 to avoid cracking by fatigue. In any case, considering the slow curing rate of these material,  
284 this needs to be confirmed for higher curing times.

285

286

287 Additionally, the UCS test results previously presented in Figure 5 for the cemented soil  
288 mixtures were normalized by the corresponding  $E_{t0}$  values in order to more clearly observe the  
289 degradation pattern of each mixture (Figure 14). The normalization of the stiffness curves  
290 enables an easier comparison between the degradation patterns of all the mixtures confirming  
291 the indications observed in Figure 5. The mixtures at 90 days, and especially M1, have clearly  
292 higher normalized modulus than the same mixtures at 28 days. This is a clear evidence of the  
293 slow rate of this cementation process and an important indication of the need to consider longer

294 curing periods for the correct characterization of the stiffness and strength properties of these  
295 alkali activated mixtures.

296

297 The unconfined compression tests results and the seismic wave measurements were analyzed  
298 together by calculating the ratio of the secant modulus at 10% of the peak deviator stress  
299 ( $E_{\text{sec10\%}}$ ) from UCS with the maximum Young's modulus ( $E_{\text{sec10\%}}/E_0$ ). This ratio presented in  
300 Table 3 gives a quantification of the degradation degree of the material, and  $E_{\text{sec10\%}}$  was selected  
301 since it is a well-defined value currently used for design purposes. The ratios between these  
302 moduli reflect that M2 evidences a stiffer response at 28 days due to its faster curing rate, as  
303 already noted in the dynamic stiffness measurements, illustrated in Figures 8 and 9. It is also  
304 worth noting that the normalized ratio of the stiffer mixture (M1) is clearly lower than M2 at  
305 28 days, inverting their relative position at 90 days, due to its stronger cementation. Comparing  
306 both curing times, is it clear that the ratio increases with longer curing periods, which is in  
307 agreement with the stiffness increase.

308

309 However, this ratio does not take into account the strain level at 10% of the peak deviator stress.  
310 Since each mixture has a different peak value,  $E_{\text{sec10\%}}$  is measured at different deviator stresses  
311 and consequently at different strain levels. For that reason, the ratio  $E_{\text{sec10\%}}/E_0$  was plotted  
312 against the average strain at that stress level, for each particular mixture, as represented in  
313 Figure 15. The data was separated by curing time (at 28 and 90 days in Figure 15a, for all  
314 mixtures) and by mixture (M1, M2 and M3 in Figure 15b, for both curing times). For each case,  
315 a power law ( $E_{\text{sec10\%}}/E_0 = A \cdot \epsilon_a^n$ ) was adjusted, which coefficient A and exponent n are  
316 summarized in Table 4, together with the corresponding correlation coefficient ( $R^2$ ). It is  
317 interesting to notice that a much higher scatter is observed for the 28 days group ( $R^2 = 0.14$ )  
318 than for the 90 days group ( $R^2 = 0.93$ ), when the bonding between particles is stronger.  
319 Analyzing the  $R^2$  for each particular mixture (Figure 15b), which are very similar, it is possible

320 to conclude that the significant difference between the  $R^2$  values obtained in Figure 15a (for 28  
321 and 90 days curing) is indeed a consequence of the specimens curing time. The strong  
322 correlation coefficients obtained (between 0.74 and 0.81), is a good indication of the adequacy  
323 of dynamic measurements in the prediction of stiffness moduli at these strain ranges.

324

325 It is also worth addressing in this discussion section, the comparison of these results with  
326 conventional soil-cement data obtained with the same soil and several cement contents and void  
327 ratios but similar molding procedures to the alkali activated mixtures. First, the values of the  
328 dynamic Young's modulus ( $E_0$ ) of the alkali activated mixtures, obtained from the seismic wave  
329 measurements, were compared with those obtained for soil-cement mixtures, reported by  
330 Amaral (2009), in Figure 16.

331

332 The results presented in Figure 16 show that the soil-cement stiffness evolution is well  
333 represented by the ACI prediction (ACI Committee 209, 1998) developed for strength, and so,  
334 this expression was used to extrapolate the soil-cement results up to 90 days of curing. The soil-  
335 cement Young's modulus stabilizes around 28 days of curing, while the alkali activated  
336 mixtures show a continuous increase well beyond that mark. This is explained by the faster  
337 dissolution rate of the calcium-type glassy material, forming C-H-S gel which can be found in  
338 cement hydration, which is a distinct cementation process of these alkali activated mixtures.

339

341

342

343 **Conclusions**

344

345 The paper highlights stiffness characteristics of a new type of cemented soil resulting from the  
346 alkaline activation of fly ash which creates a geopolymeric gel that links the soil particles. The  
347 performance of this new material was analyzed by means of unconfined compression tests,  
348 drained triaxial compression tests and seismic wave measurements, being these last two tests  
349 applied for the first time in this material. The dynamic, cyclic and static mechanical tests show  
350 a significant increase in stiffness with curing time, even beyond the 28 days of curing period.  
351 M1 mixture showed a very strong type of cementation which does not seem to be significantly  
352 affected by the confining stress nor the yielding prior to peak since very high stiffness modulus  
353 are obtained in such conditions. However, being very stiff M1 is also very fragile after the  
354 cementation bonds are broken, conversely to the other mixtures.

355

356 Compression and shear seismic wave measurements allowed the evaluation of the dynamic  
357 Poisson's ratio which revealed very interesting results. A slight decrease of this ratio in the first  
358 days of curing followed systematically by an increase of Poisson's ratio value indicated that  
359 curing may only be particularly effective after the first 7 days, conversely to what is observed  
360 in soil-cement specimens. This increase in the Poisson ratio value slightly decreases after 90  
361 days of curing stabilizing at values close to 0.2, typical of concrete.

362

363 The unconfined test secant modulus at 10% of the peak deviator stress ( $E_{sec10\%}$ ) normalized by  
364 the maximum Young's modulus ( $E_0$ ) was well adjusted by a power law in two different  
365 situations: for all mixtures at 90 days curing, and for each individual mixture considering all  
366 curing periods. This indicates that the stiffness modulus at these strain levels can be well  
367 predicted by the dynamic measurements for each mixture. Moreover, since the cemented

368 behavior tends to become more uniform with curing time, the long term stiffness modulus can  
369 be also well predicted by dynamic measurements, independently of the type of mixture.

370

371 The results point towards a similar type of cementation in both soil-cement and alkali activated  
372 mixtures, characterized by a significant increase in stiffness. The most important difference in  
373 both types of bonding lies on the curing process, since cement presents a significant increase at  
374 early ages stabilizing at 28 days, while alkali activated soil-ash mixtures show a more gradual  
375 and continuous increase, almost doubling its stiffness from 28 days to 90 days of curing.

376
